On the Intrinsic Relationship Between the Least Mean Square and Kalman Filters

The Kalman filter and the least mean square (LMS) adaptive filter are two of the most popular adaptive estimation algorithms that are often used interchangeably in a number of statistical signal processing applications. They are typically treated as separate entities, with the former as a realization of the optimal Bayesian estimator and the latter as a recursive solution to the optimal Wiener filtering problem. In this lecture note, we consider a system identification framework within which we develop a joint perspective on Kalman filtering and LMS-type algorithms, achieved through analyzing the degrees of freedom necessary for optimal stochastic gradient descent adaptation. This approach permits the introduction of Kalman filters without any notion of Bayesian statistics, which may be beneficial for many communities that do not rely on Bayesian methods [1], [2].

There are several and not immediately patent aspects of common thinking between gradient descent and recursive state-space estimators. Because of their nonobvious or awkward nature, these are often overlooked. Hopefully the framework presented in this article, with the seamless transition between LMS and Kalman filters, will provide a straightforward and unifying platform for understanding the geometry of learning and optimal parameter selection in these approaches. In addition, the material may be useful in lecture courses in statistical signal processing, or indeed, as interesting reading for the intellectually curious and generally knowledgeable reader.

**NOTATION**

Lowercase letters are used to denote scalars, e.g., $a$; boldface letters for vectors, $a$; and boldface uppercase letters for matrices, $A$. Vectors and matrices are respectively of dimensions $M \times 1$ and $M \times M$. The symbol $(\cdot)^T$ is used for vector and matrix transposition and the subscript $k$ for discrete time index. Symbol $E\{\cdot\}$ represents the statistical expectation operator, $\text{tr}\{\cdot\}$ is the matrix trace operator, and $\|\cdot\|$ the $l_2$ norm.

**PROBLEM FORMULATION**

Consider a generic system identification setting

$$d_k = x_k^T w_k^o + n_k,$$

(1)

where the aim is to estimate the unknown true system parameter vector, $w_k^o$ (optimal weight vector), which characterizes the system in (1) from observations, $d_k$, corrupted by observation noise, $n_k$. This parameter vector can be fixed, i.e., $w_k^o = w^o$, or time varying as in (1), while $x_k$ designates a zero-mean input vector and $n_k$ is a zero-mean white Gaussian process with variance $\sigma_n^2 = E\{n_k^2\}$. For simplicity, we assume that all signals are real valued.

To assist a joint discussion of state-space and regression-type models Table 1 lists the terms commonly used across different communities for the variables in the system identification paradigm in (1).

We first start the discussion with a deterministic and time-invariant optimal weight vector, $w_k^o = w^o$, and build up to the general case of a stochastic and time-varying system to give the general Kalman filter.

**PERFORMANCE EVALUATION CRITERIA**

Consider observations from an unknown deterministic system

$$d_k = x_k^T w_k^o + n_k.$$  

(2)

We desire to estimate the true parameter vector $w_k^o$ recursively, based on the existing weight vector estimate $w_{k-1}$ and the observed and input signals, i.e., $\hat{w}_k = f(w_{k-1}, d_k, x_k)$. Notice that $w_{k-1}, d_k, x_k$ are related through the output error

$$e_k = d_k - x_k^T w_{k-1}.$$  

(3)

Performance of statistical learning algorithms is typically evaluated based on the mean square error (MSE) criterion, which is defined as the output error power and is given by

$$\text{MSE} = \hat{e}_k \overset{\text{def}}{=} E\{e_k^2\}.$$  

(4)

Since our goal is to estimate the true system parameters, it is natural to also consider the weight error vector

$$\hat{w}_k \overset{\text{def}}{=} w^o - w_k,$$  

(5)

and its contribution to the output error, given by

$$e_k = x_k^T \hat{w}_k + n_k.$$  

(6)
Without loss of generality, here we treat \( x_k \) as a deterministic process, although in adaptive filtering convention it is assumed to be a zero-mean stochastic process with covariance matrix \( R = E\{x_k x_k^\top\} \). Our assumption conforms with the Kalman filtering literature, where the vector \( x_k \) is often deterministic (and sometimes even time invariant). Replacing the output error from (6) into (4) gives

\[
\xi_k = E\{(x_k^\top \hat{w}_{k-1} + n_k)^2\} = x_k^\top P_{k-1} x_k + \sigma_n^2 \quad (7a) \\
\xi_{\text{ex}} = \xi_{\text{ex},\text{c}} + \xi_{\text{ex},\text{n}}, \quad (7b)
\]

where \( P_{k-1} = E\{\hat{w}_{k-1} \hat{w}_{k-1}^\top\} \) is the symmetric and positive semidefinite weight error covariance matrix, and the noise process \( n_k \) is assumed to be statistically independent from all other variables. Therefore, for every recursion step, \( k \), the corresponding MSE denoted by \( \xi_k \) comprises two terms: 1) the time-varying excess MSE (EMSE), \( \xi_{\text{ex},\text{c}} \), which reflects the misalignment between the true and estimated weights (function of the performance of the estimator), and 2) the observation noise power, \( \xi_{\text{ex},\text{n}} = \sigma_n^2 \), which represents the minimum achievable MSE (for \( \hat{w}_k = w^o \)) and is independent of the performance of the estimator.

Our goal is to evaluate the performance of a learning algorithm in identifying the true system parameters, \( w^o \), and a more insightful measure of how closely the estimated weights, \( \hat{w}_k \), have approached the true weights, \( w^o \), is the mean square deviation (MSD), which represents the power of the weight error vector and is given by

\[
\text{MSD} = J_k = E\{\|\hat{w}_k\|^2\} = E\{\hat{w}_k^\top \hat{w}_k\} = \text{tr}\{P_k\}. \quad (8)
\]

Observe that the MSD is related to the MSE in (7a) through the weight error covariance matrix, \( P_k = E\{\hat{w}_k \hat{w}_k^\top\} \), and thus minimizing MSD also corresponds to minimizing MSE.

**OPTIMAL LEARNING GAIN FOR STOCHASTIC GRADIENT ALGORITHMS**

The LMS algorithm employs stochastic gradient descent to approximately minimize the MSE in (4) through a recursive estimation of the optimal weight vector, \( w^o \). For \( \omega_k = w_k - w^o \), the LMS solution is then given by [3]

\[
\text{LMS:} \quad w_k = w_{k-1} + \Delta w_k = w_{k-1} + \mu_k x_k e_k. \quad (9)
\]

The parameter \( \mu_k \) is a possibly time-varying positive step-size that controls the magnitude of the adaptation steps the algorithm takes; for fixed system parameters this can be visualized as a trajectory along the error surface—the MSE plot evaluated against the weight vector, \( \xi_k(w) \). Notice that the weight update \( \Delta w_k = \mu_k x_k e_k \) has the same direction as the input signal vector, \( x_k \), which makes the LMS sensitive to outliers and noise in data. Figure 1 illustrates the geometry of learning of gradient descent approaches for correlated data (elliptical contours of the error surface)—gradient descent performs locally optimal steps but has no means to follow the globally optimal shortest path to the solution, \( w^o \). It is therefore necessary to control both the direction and magnitude of adaptation steps for an algorithm to follow the shortest, optimal path to the global minimum of error surface, \( \xi (w^o) \).

The first step toward Kalman filters is to introduce more degrees of freedom by replacing the scalar step-size, \( \mu_k \), with a positive definite learning gain matrix, \( G_k \), so as to control both the magnitude and direction of the gradient descent adaptation, and follow the optimal path in Figure 1. In this way, the weight update recursion in (9) now generalizes to

\[
w_k = w_{k-1} + G_k x_k e_k. \quad (10)
\]

Unlike standard gradient-adaptive step-size approaches that minimize the MSE via \( \partial \xi_k / \partial \mu_k \) [4], [5], our aim is to introduce an optimal step-size (and learning gain) into the LMS based on the direct minimization of the MSD in (8). For convenience, we consider a general recursive weight estimator

\[
w_k = w_{k-1} + g_k e_k, \quad (11)
\]

which represents both (9) and (10), where the gain vector

\[
g_k \triangleq \begin{cases} \mu_k x_k, & \text{for the conventional LMS in (9),} \\ G_k x_k, & \text{for a general LMS in (10).} \end{cases}
\]

To minimize the MSD, given by \( J_k = E\{\|\hat{w}_k\|^2\} = \text{tr}\{P_k\} \), we first establish the weight error vector recursion for the general LMS by subtracting \( w^o \) from both sides of (11) and replacing the output error with \( e_k = x_k^\top \hat{w}_{k-1} + n_k \), to give

\[
\hat{w}_k = \hat{w}_{k-1} - g_k x_k^\top \hat{w}_{k-1} + \hat{g} x_k n_k. \quad (13)
\]

The recursion for the weight error covariance matrix, \( P_k \), is then established upon postmultiplying both sides of (13) by their
respective transposes and applying the statistical expectation operator $E\{ \cdot \}$ to both sides, to yield

$$P_k = E\{ \hat{w}_k \hat{w}_k^T \} = \text{P}_{k-1} - (x_k^T \text{P}_{k-1} x_k)_{(15)} + \mu_k (x_k^T \text{P}_{k-1} x_k + \sigma_n^2).$$

Using the well-known matrix trace identities, $\text{tr}(P_k x_k^T) = \text{tr}(P_k x_k g_k^T) = \text{tr}(g_k^T P_k x_k)$ and $\text{tr}(g_k^T g_k^T) = g_k^T g_k^T = g_k^T g_k$, the MSD evolution, $J_k = \text{tr}(P_k)$, is obtained as

$$J_k = J_{k-1} - 2 \mu_k x_k^T P_{k-1} x_k$$

$$+ \|g_k^T\| (x_k^T P_{k-1} x_k + \sigma_n^2).$$

**OPTIMAL SCALAR STEP-SIZE FOR LMS**

The standard optimal step-size approach to the LMS aims at achieving $e_{k+1|k} = d_k - x_k^T w_k = 0$, where the a posteriori error, $e_{k+1|k}$, is obtained using the updated weight vector, $w_k$, and the current input, $x_k$. The solution is known as the normalized LMS (NLMS), given by (for more details, see [6])

$$\text{NLMS: } w_k = w_{k-1} - \frac{1}{\|x_k\|} x_k e_k.$$  

The effective LMS-type step-size, $\mu_k = 1/\|x_k\|$, is now time varying and data adaptive. In practice, to stabilize the algorithm a small positive step-size $\rho_k$ can be employed, to give $\mu_k = \rho_k/\|x_k\|^2$. The NLMS is therefore conformal with the LMS, whereby the input vector, $x_k$, is normalized by its norm, $\|x_k\|^2$ (input signal power).

To find the optimal scalar step-size for the LMS in (9), which minimizes the MSD, we shall first substitute the gain $g_k = \mu k x_k$ into (15), to give the MSD recursion

$$J_k = J_{k-1} - 2 \mu_k x_k^T P_{k-1} x_k$$

$$+ \mu_k \|x_k\| (x_k^T P_{k-1} x_k + \sigma_n^2).$$

**REMARK 1**

In addition to the NLMS-type normalization factor, $1/\|x_k\|$, the optimal LMS step-size in (18) includes the correction term, $\xi_{\text{NLMS}} / \xi_k < 1$, a ratio of the EMSE, $\xi_{\text{NLMS}}$, to the overall MSE, $\xi_k$. A large deviation from the true system weights causes a large $\xi_{\text{NLMS}} / \xi_k$ and fast weight adaptation (cf. slow adaptation for a small $\xi_{\text{NLMS}} / \xi_k$). This also justifies the use of a small step-size, $\rho_k$, in practical NLMS algorithms, such as in “Variants of the LMS.”

**FROM LMS TO KALMAN FILTER**

The optimal LMS step-size in (18) aims to minimize the MSD at every time instant, however, it only controls the magnitude of gradient descent steps (see Figure 1). To find the optimal learning gain that controls simultaneously both the magnitude and direction of the gradient descent in (10), we start again from the MSD recursion [restated from (15)]

$$J_k = J_{k-1} - 2 g_k^T P_{k-1} x_k$$

$$+ \|g_k^T\| (x_k^T P_{k-1} x_k + \sigma_n^2).$$

The optimal learning gain vector, $g_k$, is then obtained by solving the above MSD for $g_k$, via $\partial J_k / \partial g_k = 0$, to give

$$g_k = \frac{P_{k-1}}{x_k^T x_{k-1} + \sigma_n^2} x_k = \frac{P_{k-1}}{\xi_k} x_k.$$

This optimal gain vector is precisely the Kalman gain [8], while the gain matrix, $G_k$, represents a ratio between the weight error covariance, $P_{k-1}$, and the MSE, $\xi_k$. A substitution into the update for $P_k$ in (14) yields a Kalman filter that estimates the time-invariant and deterministic weights, $w^\circ$, as outlined in Algorithm 1.

**REMARK 2**

For $\sigma_n^2 = 1$, the Kalman filtering equations in Algorithm 1 are identical to the recursive least squares (RLS) algorithm. In this way, this lecture note complements the classic article by Sayed and Kailath [9] that establishes a relationship between the RLS and the Kalman filter.

**SCALAR COVARIANCE UPDATE**

An additional insight into our joint perspective on Kalman and LMS algorithms is provided for independent and identically distributed system weight error vectors, whereby the diagonal weight error

**VARIANTS OF THE LMS**

To illustrate the generality of our results, consider the NLMS and the regularized NLMS (also known as $\epsilon$-NLMS), given by

$$\text{NLMS: } w_k = w_{k-1} - \rho_k x_k e_k.$$  

$$\epsilon - \text{NLMS: } w_k = w_{k-1} - \frac{1}{\|x_k\| + \epsilon_k} x_k e_k$$

where $\rho_k$ is a step-size and $\epsilon_k$ a regularization factor. Based on (17) and (18), the optimal values for $\rho_k$ and $\epsilon_k$ can be found as

$$\rho_k = \frac{x_k^T P_{k-1} x_k}{x_k^T P_{k-1} x_k + \sigma_n^2}$$

$$+ \epsilon_k \|x_k\|^2 \sigma_n^2.$$  

Upon substituting $\rho_k$ and $\epsilon_k$ from (53) into their respective weight update recursions in (51) and (52), we arrive at

$$w_k = w_{k-1} + \frac{x_k^T P_{k-1} x_k}{x_k^T P_{k-1} x_k + \sigma_n^2} \|x_k\| e_k.$$  

for both the NLMS and $\epsilon$-NLMS, which is identical to the LMS with the optimal step-size in (18). Therefore, the minimization of the mean square deviation with respect to the parameter: 1) $\mu_k$ in the LMS, 2) $\rho_k$ in the NLMS, and 3) $\epsilon_k$ in the $\epsilon$-NLMS, yields exactly the same algorithm, which is intimately related to the Kalman filter, as shown in Table 2 and indicated by the expression for the Kalman gain, $g_k$. 

IEEE SIGNAL PROCESSING MAGAZINE | 119 | NOVEMBER 2015
Algorithm 1: The Kalman filter for deterministic states.

At each time instant $k > 0$, based on measurements $\{d_k, x_k\}$

1) Compute the optimal learning gain (Kalman gain):
\[
g_k = P_{k-1} x_k / (x_k^T P_{k-1} x_k + \sigma_n^2) \]

2) Update the weight vector estimate:
\[
w_k = w_{k-1} + g_k (d_k - x_k^T w_{k-1})
\]

3) Update the weight error covariance matrix:
\[
P_k = P_{k-1} - g_k x_k^T P_{k-1}
\]

Remark 3

A physical interpretation of the regularization parameter, $\epsilon_k$, is that it models our confidence level in the current weight estimate, $w_k$, via a ratio of the algorithm-independent minimum MSE, $\xi_{\min} = \sigma_n^2$, and the algorithm-specific weight error variance, $\sigma_{\hat{w}_k}^2$. The more confident we are in current weight estimates, the greater the value of $\epsilon_k$ and the smaller the magnitude of the weight update, $\Delta w_k = g_k \epsilon_k$.

Algorithm 2: A hybrid Kalman-LMS algorithm.

At each time instant $k > 0$, based on measurements $\{d_k, x_k\}$

1) Compute the confidence level (regularization parameter):
\[
\epsilon_k = \sigma_n^2 / \sigma_{\hat{w}_k}^2
\]

2) Update the weight vector estimate:
\[
w_k = w_{k-1} + x_k / \|x_k\|^2 + \epsilon_k (d_k - x_k^T w_{k-1})
\]

3) Update the weight error covariance matrix:
\[
P_k = P_{k-1} - \frac{\epsilon_k}{\|x_k\|^2 + \epsilon_k} \sigma_{\hat{w}_k}^2
\]

Remark 4

The form of the LMS algorithm outlined in Algorithm 2 is identical to the class of generalized normalized gradient descent (GNGD) algorithms in [5] and [10], which update the regularization parameter, $\epsilon_k$, using stochastic gradient descent. More recently, Algorithm 2 was derived independently in [11] as an approximate probabilistic filter for linear Gaussian data and is referred to as the probabilistic LMS.

From Optimal LMS to General Kalman Filter

To complete the derivation, since $P_k = \sigma_{\hat{w}_k}^2 I$ and $tr\{P_k\} = M \sigma_{\hat{w}_k}^2$, the MSD recursion in (15) now becomes
\[
\sigma_{\hat{w}_k}^2 = \sigma_{\hat{w}_{k-1}}^2 - \frac{\|x_k\|^2}{M (\|x_k\|^2 + \epsilon_k)} \sigma_{\hat{w}_{k-1}}^2.
\]

The resulting hybrid “Kalman-LMS” algorithm is given in Algorithm 2.

Figure 2: The time-varying state transition in (22a) results in a time-varying MSE surface. For clarity, the figure considers a scalar case without state noise. Within the Kalman filter, the prediction step in (23b) preserves the relative position of $w_{k+1|k}$ with respect to the evolved true state, $w_{k+1}$.
the general Kalman filter in (23a) and (23b) employs its prediction step in (23b) to track the time-varying error surface, a “frame of reference” for optimal adaptation.

The update steps (indicated by the index $k | k$) and the prediction steps (index $k + 1 | k$) for all the quantities involved are defined below as

$$\tilde{w}_{k | k} \overset{\text{def}}{=} w_{k} - w_{k | k},$$
$$P_{k | k} \overset{\text{def}}{=} E\{ \tilde{w}_{k | k} \tilde{w}_{k | k}^T \},$$
$$\tilde{w}_{k+1 | k} \overset{\text{def}}{=} \tilde{w}_{k+1 | k} - w_{k+1 | k} = F_{k} \tilde{w}_{k | k} + q_{k},$$
$$P_{k+1 | k} \overset{\text{def}}{=} E\{ \tilde{w}_{k+1 | k} \tilde{w}_{k+1 | k}^T \} = F_{k} P_{k | k} F_{k}^T + Q_{k}. \quad (24)$$

Much like (13)–(17), the Kalman gain is derived based on the weight error vector recursion, obtained by subtracting the optimal time-varying $w_{k}$ from the state update in (23a), to yield

$$\tilde{w}_{k | k} = w_{k | k} - g_{k} x_{k}^{T} \tilde{w}_{k | k} - g_{k} n_{k}. \quad (25)$$

so that the evolution of the weight error covariance becomes

$$P_{k | k} \overset{\text{def}}{=} E\{ \tilde{w}_{k | k} \tilde{w}_{k | k}^T \} = P_{k | k-1} -(P_{k | k-1} x_{k} g_{k}^T + g_{k} x_{k}^T P_{k | k-1}) + g_{k} g_{k}^T (x_{k} x_{k}^T P_{k | k-1} x_{k} + \sigma_{o}^{2}). \quad (26)$$

Finally, the Kalman gain, $g_{k}$, which minimizes the MSD, $J_{k | k} = tr\{P_{k | k}\}$, is obtained as

$$g_{k} = -\frac{P_{k | k-1}}{x_{k}^{T} P_{k | k-1} x_{k} + \sigma_{o}^{2}} x_{k} = G_{k} x_{k}. \quad (27)$$

which is conformal with the optimal LMS gain in (19). The general Kalman filter steps are summarized in Algorithm 3.

**REMARK 5**

Steps 1–3 in Algorithm 3 are identical to the deterministic Kalman filter that was derived starting from the LMS and is described in Algorithm 1. The essential difference is in steps 4 and 5, which cater for the time-varying and stochastic general system weights. Therefore, the fundamental principles of the Kalman filter can be considered through optimal adaptive step-size LMS algorithms.

**CONCLUSIONS**

We have employed “optimal gain” as a mathematical lens to examine conjointly variants of the LMS algorithms and Kalman filters. This perspective enabled us to create a framework for unification of these two main classes of adaptive recursive online estimators. A close examination of the relationship between the two standard performance evaluation measures, the MSE and MSD, allowed us to intuitively link up the geometry of learning of Kalman filters and LMS, within both deterministic and stochastic system identification settings. The Kalman filtering algorithm is then derived in an LMS-type fashion via the optimal learning gain matrix, without resorting to probabilistic approaches [12].

Such a conceptual insight permits seamless migration of ideas from the state-space-based Kalman filters to the LMS adaptive linear filters and vice versa and provides a platform for further developments, practical applications, and nonlinear extensions [13]. It is our hope that this framework of examination of these normally disparate areas will both demystify recursive estimation for educational purposes [14, 15] and further empower practitioners with enhanced intuition and freedom in algorithmic design for the manifold applications.
